Time-Series Regression and Generalized Least Squares in R*

An Appendix to An R Companion to Applied Regression, third edition

John Fox & Sanford Weisberg

last revision: 2018-09-26

Abstract

Generalized least-squares (GLS) regression extends ordinary least-squares (OLS) estimation of the normal linear model by providing for possibly unequal error variances and for correlations between different errors. A common application of GLS estimation is to time-series regression, in which it is generally implausible to assume that errors are independent. This appendix to Fox and Weisberg (2019) briefly reviews GLS estimation and demonstrates its application to time-series data using the gls() function in the nlme package, which is part of the standard R distribution.

1 Generalized Least Squares

In the standard linear model (for example, in Chapter 4 of the *R Companion*),

$$E(\mathbf{y}|\mathbf{X}) = \mathbf{X}\boldsymbol{\beta}$$

or, equivalently

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$$

where \mathbf{y} is the $n \times 1$ response vector; \mathbf{X} is an $n \times k + 1$ model matrix, typically with an initial column of 1s for the regression constant; $\boldsymbol{\beta}$ is a $k+1\times 1$ vector of regression coefficients to estimate; and $\boldsymbol{\varepsilon}$ is an $n\times 1$ vector of errors. Assuming that $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I}_n)$, or at least that the errors are uncorrelated and equally variable, leads to the familiar ordinary-least-squares (OLS) estimator of $\boldsymbol{\beta}$,

$$\mathbf{b}_{\mathrm{OLS}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}$$

with covariance matrix

$$Var(\mathbf{b}_{OLS}) = \sigma^2 (\mathbf{X}'\mathbf{X})^{-1}$$

More generally, we can assume that $\varepsilon \sim N_n(\mathbf{0}, \Sigma)$, where the error covariance matrix Σ is symmetric and positive-definite. Different diagonal entries in Σ error variances that are not necessarily all equal, while nonzero off-diagonal entries correspond to correlated errors.

Suppose, for the time-being, that Σ is known. Then, the log-likelihood for the model is

$$\log L(\boldsymbol{\beta}) = -\frac{n}{2} \log 2\pi - \frac{1}{2} \log(\det \boldsymbol{\Sigma}) - \frac{1}{2} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})' \boldsymbol{\Sigma}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$$

which is maximimized by the generalized-least-squares (GLS) estimator of β ,

$$\mathbf{b}_{\mathrm{GLS}} = (\mathbf{X}'\mathbf{\Sigma}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Sigma}^{-1}\mathbf{y}$$

with covariance matrix

$$Var(\mathbf{b}_{GLS}) = (\mathbf{X}'\mathbf{\Sigma}^{-1}\mathbf{X})^{-1}$$

For example, when Σ is a diagonal matrix of (generally) unequal error variances, then \mathbf{b}_{GLS} is just the weighted-least-squares (WLS) estimator, which can be fit in R by the lm() function, specifying the weights arguments (see, e.g., Section 4.9.4 of the R Companion).

In a real application, of course, the error covariance matrix Σ is not known, and must be estimated from the data along with the regression coefficients β . However, Σ has up to n(n+1)/2 free elements, so this general model has more parameters than data points. To make progress we require restrictions on the elements of Σ .

2 Serially Correlated Errors

One common context in which the errors from a regression model are unlikely to be independent is in *time-series* data, where the cases represent different moments or intervals of time, usually equally spaced. We will assume that the process generating the regression errors is *stationary*: That is, all of the errors have the same expectation (already assumed to be 0) and the same variance (σ^2), and the covariance of two errors depends only upon their separation s in time:¹

$$C(\varepsilon_t, \varepsilon_{t+s}) = C(\varepsilon_t, \varepsilon_{t-s}) = \sigma^2 \rho_s$$

where ρ_s is the error autocorrelation at lag s.

In this situation, the error covariance matrix has the following structure:

$$\Sigma = \sigma^{2} \begin{bmatrix} 1 & \rho_{1} & \rho_{2} & \cdots & \rho_{n-1} \\ \rho_{1} & 1 & \rho_{1} & \cdots & \rho_{n-2} \\ \rho_{2} & \rho_{1} & 1 & \cdots & \rho_{n-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \rho_{n-1} & \rho_{n-2} & \rho_{n-3} & \cdots & 1 \end{bmatrix} = \sigma^{2} \mathbf{P}$$

If we knew the values of σ^2 and the ρ s, then we could apply this result to find the GLS estimator of β in a time-series regression, but, of course, these are generally unknown parameters. Moreover, while they are many fewer than the number of elements in the unrestricted error covariance matrix Σ , the large number (n-1) of different ρ s makes their estimation (along with σ^2) impossible without specifying additional structure for the autocorrelated errors.

There are several standard models for stationary time-series; the most common for autocorrelated regression errors is the *first-order auto-regressive process*, AR(1):

$$\varepsilon_t = \phi \varepsilon_{t-1} + \nu_t$$

where the random shocks ν_t are assumed to be Gaussian white noise, NID(0, σ_{ν}^2). Under this model, $\rho_1 = \phi$, $\rho_s = \phi^s$, and $\sigma^2 = \sigma_{\nu}^2/(1-\phi^2)$. Since we must have $|\phi| < 1$, the error autocorrelations ρ_s decay exponentially towards 0 as s increases.²

Higher-order autoregressive models are a direct generalization of the first-order model; for example, the second-order autoregressive model, denoted AR(2), is

$$\varepsilon_t = \phi_1 \varepsilon_{t-1} + \phi_2 \varepsilon_{t-2} + \nu_t$$

In contrast, in the first-order moving-average process, MA(1), the current error depends upon the random shock from the current and previous periods (rather than upon the previous regression error),

$$\varepsilon_t = \nu_t + \psi \nu_{t-1}$$

¹Adjacent cases are taken by convention to be separated by 1 unit of time—e.g., 1 year in annual time-series data. ²For the AR(1) process to be stationary, $|\phi|$ cannot be equal to 1.

and higher-order MA(q) processes are similarly defined. Finally, AR and MA terms are combined in ARMA(p,q) processes; for example, ARMA(1,1) errors follow the process

$$\varepsilon_t = \phi \varepsilon_{t-1} + \nu_t + \psi \nu_{t-1}$$

Examining the residual autocorrelations from a preliminary OLS regression can suggest a reasonable form for the error-generating process.³ The lag-s residual autocorrelation is

$$r_s = \frac{\sum_{t=s+1}^{n} e_t e_{t-s}}{\sum_{t=1}^{n} e_t^2}$$

If the residuals were independently distributed (which they are not), the standard error of each r_s would be approximately $1/\sqrt{n}$, a quantity that can be used as a rough guide to the sampling variability of the residual autocorrelations. A more accurate approach to testing hypotheses about autocorrelated errors is to calculate the *Dubin-Watson statistics*,

$$D_s = \frac{\sum_{t=s+1}^{n} (e_t - e_{t-s})^2}{\sum_{t=1}^{n} e_t^2}$$

which have a known, if complex, sampling distribution that depends upon the model matrix \mathbf{X} . When the sample size is large, $D_s \approx 2(1-r_s)$, and so Durbin-Watson statistics near 2 are indicative of small residual autocorrelation, those below 2 of positive autocorrelation, and those above 2 of negative autocorrelation.

3 Using The gls() Function in R

The gls() function in the **nlme** package (Pinheiro et al., 2018), which is part of the standard R distribution, fits regression models with a variety of correlated-error and non-constant error-variance structures.⁴ To illustrate the use of gls(), let us examine time-series data on women's crime rates in Canada, analyzed by Fox and Hartnagel (1979). The data are in the Hartnagel data set in the carData package, which we load along with the car package:⁵:

library("car")

Loading required package: carData

brief (Hartnagel, c(6, 2))

38 x 8 data.frame (30 rows omitted)

	year	tfr	partic	degrees	fconvict	ftheft	mconvict	mtheft
	[i]	[i]	[i]	[n]	[n]	[n]	[n]	[n]
1	1931	3200	234	12.4	77.1	NA	778.7	NA
2	1932	3084	234	12.9	92.9	NA	745.7	NA
3	1933	2864	235	13.9	98.3	NA	768.3	NA

³In identifying an ARMA process, it helps to look as well at the *partial autocorrelations* of the residuals. For example, an AR(1) process has an exponentially decaying autocorrelation function, and a partial autocorrelation function with a single nonzero spike at lag 1. Conversely, an MA(1) process has an exponentially decaying *partial autocorrelation* function, and an *autocorrelation* function with a single nonzero spike at lag 1. Of course, these neat theoretical patterns are subject to sampling error.

⁴The **nlme** package also has functions for fitting linear and nonlinear mixed models, as described in Chapter 7 of the *R Companion* and the on-line appendix on nonlinear regression.

⁵R functions used but not described in this appendix are discussed in ?. All the R code used in this appendix can be downloaded from http://tinyurl.com/carbook. Alternatively, if you are running R and attached to the internet, load the car package and enter the command carWeb(script="appendix-timeseries").

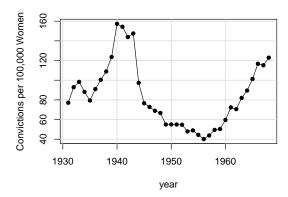

Figure 1: Time series of Canadian women's indictable-offense conviction rate, 1931–1968.

	4	1934	2803	237	13.6	88.1	NA	733.6	NA		
	5	1935	2755	238	13.2	79.4	20.4	765.7	247.1		
	6	1936	2696	240	13.2	91.0	22.1	816.5	254.9		
	37	1967	2586	339	80.4	115.2	70.6	781.1	272.0		
	38	1968	2441	338	90.4	122.9	73.0	849.7	274.7		

The variables in the data set are as follows:

- year, 1931-1968.
- tfr, the total fertility rate, births per 1000 women.
- partic, women's labor-force participation rate, per 1000.
- degrees, women's post-secondary degree rate, per 10,000.
- fconvict, women's indictable-offense conviction rate, per 100,000.
- ftheft, women's theft conviction rate, per 100,000.
- mconvict, men's indictable-offense conviction rate, per 100,000.
- mtheft, men's theft conviction rate, per 100,000.

We will estimate the regression of fconvict on tfr, partic, degrees, and mconvict. The rationale for including the last predictor is to control for omitted variables that affect the crime rate in general. Let us begin by examining the time series for the women's conviction rate (Figure 1):

```
plot(fconvict ~ year, type="n",data=Hartnagel,
    ylab="Convictions per 100,000 Women")
grid(lty=1)
with(Hartnagel, points(year, fconvict, type="o", pch=16))
```

To add grid lines, we used a sequence of commands to draw this graph.⁶ First the plot() function is used to set up axes and labels. The argument type="n" suppresses drawing any points. The

⁶See Chapter 9 of the *R Companion* for general information about drawing graphs in R.

function grid() adds grid lines before adding points and lines. The call to points() adds both points and lines, with arguments type="o" to overplots points and lines, as is traditional for a time-series graph, and pch=16 to use filled dots as the plotting characters. We can see that the women's conviction rate fluctuated substantially but gradually during this historical period, with no apparent overall trend.

A preliminary OLS regression produces the following fit to the data:

```
mod.ols <- lm(fconvict ~ tfr + partic + degrees + mconvict, data=Hartnagel)
summary(mod.ols)</pre>
```

Call:

```
lm(formula = fconvict ~ tfr + partic + degrees + mconvict, data = Hartnagel)
```

Residuals:

```
Min 1Q Median 3Q Max -42.96 -9.20 -3.57 6.15 48.38
```

Coefficients:

```

```

The women's crime rate, therefore, appears to decline with fertility and increase with labor-force participation; the coefficients for the other two predictors have large p-values. A graph of the residuals from the OLS regression (Figure 2), however, suggests that they may be substantially autocorrelated:⁸

The acf() function in the R stats package computes and plots the autocorrelation and partial-autocorrelation functions of a time series, here for the OLS residuals (Figure 3), because the residuals vary systematically with time:

```
acf(residuals(mod.ols))
acf(residuals(mod.ols), type="partial")
```

The broken horizontal lines on the plots correspond to approximate 95% confidence limits. The general pattern of the autocorrelation and partial autocorrelation functions—sinusoidal decay in the

⁷There is a ts.plot() function in the stats package in R for graphing time-series data. Although we will not need them, it is also possible to define special time-series data objects in R. For more information, consult ?ts.

⁸There also seems to be something unusual going on during World War II that is not accounted for by the predictors, a subject that we will not pursue here.

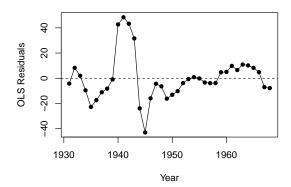

Figure 2: Residuals from the OLS regression of women's conviction rate on several predictors.

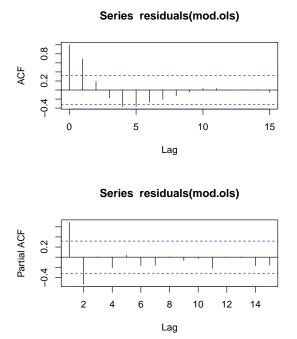

Figure 3: Autocorrelation and partial-autocorrelation functions for the residuals from the OLS regression of women's conviction rate on several predictors.

former; two spikes, one positive, the other negative, in the latter—is suggestive of an AR(2) process with $\phi_1 > 0$ and $\phi_2 < 0$.

We follow up by computing Durbin-Watson statistics for the OLS regression, using the durbin-WatsonTest() function in the **car** package. By default, this function computes bootstrapped p-values for the Durbin-Watson statistics:⁹

durbinWatsonTest(mod.ols, max.lag=5)

```
lag Autocorrelation D-W Statistic p-value
  1
            0.68834
                           0.61686
                                     0.000
  2
            0.19227
                           1.59936
                                     0.124
  3
           -0.16857
                           2.31874
                                     0.312
  4
           -0.36528
                           2.69905
                                     0.010
  5
           -0.36732
                           2.65211
                                     0.014
Alternative hypothesis: rho[lag] != 0
```

Three of the first five Durbin-Watson statistics have small p=values, including the first. As an alternative, the dwtest() function in the lmtest package (Zeileis and Hothorn, 2002) computes the p-value for the first-order Durbin-Watson statistic analytically:

```
library("lmtest")
Loading required package: zoo
Attaching package: 'zoo'
The following objects are masked from 'package:base':
    as.Date, as.Date.numeric
dwtest(mod.ols, alternative="two.sided")
```

Durbin-Watson test

```
data: mod.ols
DW = 0.617, p-value = 1.4e-08
alternative hypothesis: true autocorrelation is not 0
```

Many of the arguments for the gls() function are the same as for lm()—in particular, gls() takes model, data, subset, and na.action arguments.

- In gls(), na.action defaults to na.fail: Missing data in a time-series in any event require special consideration.
- The weights argument to gls() can be used to specify a model for the error variance,
- As we will illustrate presently, the correlation argument can be used to specify a model for error autocorrelation.
- The method argument selects the method of estimation method="ML" for maximum-likelihood estimation.

 $^{^9\}mathrm{See}$ Section 5.2.2 of the R Companion and the on-line appendix on bootstrapping.

¹⁰The default method for gls() is "REML" for REstricted Maximum-Likelihood, which may be thought of as correcting for degrees of freedom. In the current illustration, REML estimation produces rather different results from ML. (Try it!) To see the full range of arguments to gls(), consult the on-line help.

For the Canadian women's crime data:

```
library("nlme")
mod.gls <- gls(fconvict ~ tfr + partic + degrees + mconvict,</pre>
    data=Hartnagel, correlation=corARMA(p=2), method="ML")

```

Specifying the correlation structure as correlation=corARMA(p=2) fits an AR(2) process for the errors; that is, the moving-average component is implicitly of order q=0, and hence is absent. In this instance, the ML estimates of the regression parameters under the AR(2) error-correlation model are not terribly different from the OLS estimates, although the coefficient for mconvict now has a smaller p-value. The ML estimates of the error-autoregressive parameters are sizable, $\hat{\phi}_1 = 1.068$ and $\hat{\phi}_2 = -0.551$.

We can employ likelihood-ratio tests to check whether the parameters of the AR(2) process for the errors are necessary, and whether a second-order autoregressive model is sufficient. We proceed by updating the original "gls" model, respecifying the time-series process for the errors; we then compare nested models using the generic anova() function, which has a method for "gls" objects:

```
mod.gls.3 <- update(mod.gls, correlation=corARMA(p=3))</pre>
mod.gls.1 <- update(mod.gls, correlation=corARMA(p=1))</pre>
mod.gls.0 <- update(mod.gls, correlation=NULL)</pre>

An AR(3) specification would be unusually complicated, but in any event the tests support the AR(2) specification.

4 Complementary Reading and References

Time-series regression and GLS estimation are covered in Fox (2016, Chap. 16). GLS estimation is a standard topic in econometrics texts. There are substantial treatments in Judge et al. (1985) and in Greene (2018), for example. Likewise, ARMA models are a standard topic in the time-series literature; see, for example, Chatfield (2003). Time-series regression is also a much larger topic than GLS estimation of linear models with autocorrelated errors; in additions to the references cited above, see Pickup (2015) for a broad and accessible overview with social-science examples.
